Abstract

Tree species is one of the most important determinants of wood-inhabiting fungal community composition, yet its relationship with fungal reproductive and dispersal traits remains poorly understood. We studied fungal communities (total of 657 species) inhabiting broadleaved and coniferous dead wood (total of 192 logs) in 12 semi-natural boreal forests. We utilized a trait-based hierarchical joint species distribution model to examine how the relationship between dead wood quality and species occurrence correlates with reproductive and dispersal morphological traits. Broadleaved trees had higher species richness than conifers, due to discomycetoids and pyrenomycetoids specializing in them. Resupinate and pileate species were generally specialized in coniferous dead wood. Fungi inhabiting broadleaved trees had larger and more elongated spores than fungi in conifers. Spore size was larger and spore shape more spherical in species occupying large dead wood units. These results indicate the selective effect of dead wood quality, visible not only in species diversity, but also in reproductive and dispersal traits.

Index descriptors: broadleaved, coniferous, dead wood, functional trait, fruitbody, morphology, specialization, spore, tree species

INTRODUCTION

Functional traits in fungi can be defined as any morphological, physiological or phenological feature affecting the fitness of an individual fungus (Dawson et al., 2018). Knowledge of the relationship between species traits and species responses to environmental conditions provides understanding of the mechanisms influencing community assembly in different environments (McGill et al., 2006; Weiher et al., 2011). Although trait-based assessments of community-level responses in the fungal kingdom have lagged behind that of animal and plant communities, currently fungal ecological research is undergoing a proliferation of empirical and conceptual studies addressing this issue (Aguilar-Trigueros et al., 2015; Crowther et al., 2014; Dawson et al., 2018; Peay et al., 2008).

Wood-inhabiting fungi constitute a highly species-rich and functionally important group regulating nutrient cycling in forest ecosystems (Boddy et al., 2008; Dowding, 1981; Kahl et al., 2017; Stokland et al., 2012). Wood-inhabiting fungal communities strongly respond to changes in environmental variables such as climatic conditions (Bässler et al., 2010; Boddy and Heilmann-Clausen, 2008; Heilmann-Clausen et al., 2014; Heilmann-Clausen and Christensen, 2005; Lindblad, 2001; Pouska et al., 2017), resource quality (Abrego and Salcedo, 2013; Juutilainen et al., 2017; Küffer et al., 2008; Renvall, 1995) and habitat naturalness (Abrego and Salcedo, 2014; Bader et al., 1995; Lõhmus, 2011; Sippola et al., 2001; Sippola and Renvall, 1999). Given the strong responses of wood-inhabiting fungal communities to the environment and their high taxonomical and morphological diversity, many recent studies have focused on understanding how fungal functional diversity is influenced by environmental conditions (e.g. Abrego et al., 2017; Bässler et al., 2014; Caiafa et al., 2017; Calhim et al., 2018; Kauserud et al., 2011; Nordén et al., 2013; Norros et al., 2015).

Traits related to spore and fruitbody morphology are among the very few traits that are comprehensively available for wood-inhabiting fungi (Dawson et al., 2018). In previous studies, these traits have been found to be important in determining the occurrences of fungal species on dead wood of different sizes and decay stages (Abrego et al., 2017; Nordén et al., 2013). In terms of fruitbody morphology, wood-inhabiting fungal species with robust pileate and resupinate fruitbodies have been found to require large dead wood (Abrego et al., 2017; Bässler et al., 2016), while fungi with ramarioid fruitbodies and resupinate polypores require strongly decayed wood (Abrego et al., 2017). In terms of spore morphology, dead wood in advanced decay stages harbours more wood-inhabiting fungal species with thick-walled and ornamented spores (Abrego et al., 2017). The links between spore size and dead wood characteristics, however, remain unresolved. Nordén et al. (2013) found that spore size slightly decreased as log size increased, while Abrego et al. (2017) discovered that larger logs hold species with somewhat larger spores. The discrepancy in the results between the cited studies most likely arises from the differences in the taxonomical coverage and host-tree species.

Host-tree identity is an important determinant of the species composition of wood-inhabiting fungal communities (Krah et al., 2018b; Lumley et al., 2001; Ordynets et al., 2018; Rajala et al., 2010). In some cases, host-tree identity can determine wood-inhabiting fungal diversity more than microclimatic conditions and local dead wood amount or heterogeneity (Krah et al., 2018b). In general, broadleaved and coniferous dead trees hold quite distinct fungal communities, broadleaved trees being more species rich (Abrego et al., 2016; Rajala et al., 2010; Stokland, 2012a). According to Rajala et al. (2010), the higher species richness in broadleaved trees results from a higher diversity of Ascomycota. In spite of the clear influence of host-tree species on wood-inhabiting fungal community composition, to our knowledge, the effect of host tree identity on the functional composition of wood-inhabiting fungal communities has not been thoroughly investigated (but see Kauserud et al., 2008 for polypores).

Fennoscandian boreal forests represent a suitable ecosystem for studying the effect of host-tree identity on wood-inhabiting fungal communities. These forests are composed of a relatively small set of broadleaved and coniferous tree species, which all produce high amounts of dead wood (Esseen et al., 1997; Siitonen, 2001). In the southern boreal zone in Finland, (Ahti et al., 1968), the dominant tree species are Norway spruce (*Picea abies*, hereafter called spruce), Scots pine (*Pinus sylvestris*, pine), birches (*Betula* spp.) and European aspen (*Populus tremula,* aspen). While the fungal communities inhabiting dead spruce wood have been extensively studied (Edman et al., 2004; Kruys et al., 1999; Kubartová et al., 2012; Ottosson et al., 2015), the fungal communities inhabiting the other dominant tree species, especially birch and aspen, have been less studied (but see Lumley et al. 2001; Rajala et al. 2010; Ruokolainen et al. 2018).

The main aim of the present study is to evaluate how host-tree characteristics relate to the morphological composition of fruiting wood-inhabiting fungi. For this, we use an extensive dataset consisting of 657 species of non-lichenized fungi producing sexual fruitbodies. We surveyed large logs (base diameter > 15 cm) belonging to the four dominant tree species in Fennoscandian boreal forests (spruce, pine, birch and aspen) in 12 seminatural forest sites. More specifically, we determine how much of the variation in species occurrences is explained by the host-tree species and volume, and how much of the variation in community composition is explained by the morphological characteristics of the fruitbodies and spores.

We expected differences in trait composition to arise from the differences in the wood composition and distributional patterns of coniferous versus broadleaved trees. Coniferous and broadleaved wood differ in their chemical and physical characteristics, coniferous wood having generally higher amounts of toxic compounds for saproxylic organisms (Stokland, 2012a). In terms of distributional patterns, in Finnish boreal forests broadleaved trees are less abundant and show more clumped distributions than coniferous trees. Thus, the fungal species growing on each of the wood types should be well adapted to colonize and exploit the wood resources accordingly.

We hypothesized that the manner by which species exploit the wood resources is reflected in the morphological traits, as these may be linked to resource-use and dispersal strategies. Our main working hypotheses related to fruitbody morphology are: 1) species producing small-sized fruitbodies, such as some Ascomycota, are most prevalent on broadleaved wood because unlike other fungi, they are able to decompose bark through soft rot, and bark is more abundant in decomposing broadleaved logs than in coniferous logs; 2) Agaricoids are most prevalent on broadleaved wood, because they have lignin-decomposing enzymes (causing white rot) which are especially efficient in exploiting wood of broadleaved trees (Krah et al., 2018a); 3) Species with pileate and resupinate fruitbodies are expected to be equally prevalent in broadleaved and coniferous logs, because these include lineages which equally well decompose cellulose and mostly occur on coniferous logs (i.e. brown-rot fungi), or mainly decompose lignin and mostly occur on broadleaved logs (i.e. white-rot fungi) (Krah et al., 2018a). Our working hypothesis about how spore morphology is linked to host tree is that 4) coniferous trees host species with smaller spores because their wood is easier to penetrate, compared to wood of broadleaved trees (Kauserud et al., 2008); and 5) broadleaved trees with clumped distributions in the forest landscape (e.g. aspen) also have species with small-sized spores, because they should be able to disperse longer distances (Norros et al., 2014).

MATERIALS AND METHODS

Study sites and design

We carried out the study in central Finland, which belongs to the southern boreal vegetation zone (Ahti et al., 1968). All of the 12 study sites were spruce dominated forests characterized by *Myrtillus* or *Oxalis-Myrtillus* forest types (Cajander, 1949). All study sites were seminatural, and varied relatively little in their age and management history. To control for the quality variation among the study sites in the analyses, we used a forest naturalness index described in Supplementary material 1. From each forest, we chose four large (base diameter ≥ 15cm), naturally died, fallen logs of birch, spruce, pine and aspen (these species produce the majority of the coarse dead wood (diameter at breast height >10cm) in the area), in total 16 logs at each site and 192 logs in the whole study. To minimize the variation in log quality, only logs that had their decay stage between 2-4 (Renvall, 1995), and moss cover < 50% were selected. For each log, we measured the base and top diameter and the length of the logs, and calculated the volume by using the formula of a truncated cone.

Fungal data collection and identification

We thoroughly surveyed the fungal sexual fruitbodies on each study log. All fruitbodies from the same taxon within a study log were considered as one occurrence of the taxon. To better account for the species-specific variation in the timing and duration of fruitbody production (see Purhonen et al., 2017), two subsequent inspections were conducted for each log. The first inspection was performed between 21st of May and 6th of June, and the second between 20th of August and 26th of September. To enable multiple surveys of the same logs, moss and bark cover was left intact and the logs were not turned over. The fruitbodies were identified to species in the field or collected for microscopic identification (about 7500 specimens collected). When the species-level identification was not possible, we identified the specimens to the highest possible taxonomical level and named them with unique labels according to their morphology (e.g. pyrenomycete sp1, sp2 etc.). Some of the classified taxa include multiple species (i.e. species complexes), as their taxonomy is still unresolved. The nomenclature follows Index fungorum (Royal Botanic Gardens Kew et al., 2016).

Fungal trait data collection

The identified species were classified into seven groups according to their fruitbody morphology; agaricoids were species having a soft pileus and stipe (also pleurotoid fungi were grouped here). As discomycetoids, we classified species with disc- to cup-shaped fruitbodies. Pileates were species that grow as crusts over the log surface when young but majority of the fruitbody is a pileus or erected on the edges when adults. As pyrenomycetoids, we classified those fungi of which fruitbodies were organized in individual round or flask shaped bags (i.e. perithecia). Ramarioids had fruitbodies with branched structure. As resupinates, we classified those species that mostly grow as a crust over the log surface, but some may be slightly pileate as well. Stromatoids were fungi whose fruitbodies are organized round or flask shaped bags embedded in a hard mass-like structure.

For the spore morphology, we gathered information about spore length, width and presence of ornamentation (meaning that the surface of the spore is not smooth but has some texture) from the literature. For those specimens that we could only identify to the genus level, but still recognize as unique taxa, we measured the spore size and noted the shape during the identification procedure (see detailed description of the trait variable in Table 2.). The literature used for the spore morphology is listed in Supplementary Material 2.

To account for phylogenetic relationships between species, the phylogenetic relationships were estimated based on the taxonomic levels. As the data include a large number of poorly known species and species that are not yet described, it was not possible to use a quantitative phylogenetic tree. For each species, we included the taxonomic levels of the genus, family, order and class, using the Index Fungorum and Mycobank online databases (International Mycological Association, 2017; Royal Botanic Gardens Kew et al., 2017).

Statistical analyses

We analyzed the data with Hierarchical Modelling of Species Communities (HMSC; Ovaskainen et al., 2017). HMSC is a joint species distribution modelling framework (Warton et al., 2015) that enables the integration of data on species occurrences or abundances, environmental covariates, species traits and phylogenetic relationships, as well as the spatio-temporal nature of the study design (Ovaskainen et al., 2017).

In the HMSC analyses, the $n_y \times n_s$ response matrix **Y** consisted of presence-absences of the $n_s = 657$ species observed in the $n_y = 192$ logs, called henceforth sampling units. We modelled **Y** with probit-regression, including in the predictor matrix **X** the environmental covariates of the tree species (categorical variable with four levels: aspen, birch, spruce and pine), the size of the dead wood unit (log-transformed volume), decay class (categorical variable with two levels: decay class 2; and decay classes 3 and 4 combined, as only four logs had decay class four), and the forest naturalness index. We modelled the mapping from **X** to **Y** as a function of species traits and phylogenetic relationships following Abrego et al. (2017) and Ovaskainen et al. (2017). We included in the matrix of species traits **T** the fruitbody morphology (categorical variable with seven levels: agaricoid, discomycetoid, pileate, pyrenomycetoid, ramarioid, resupinate, stromatoid), the presence of ornamentation in the spores (categorical variable with two levels: yes or no), spore shape (log-transformed ratio of length to width), and spore size (log-transformed volume). In the absence of a quantitative phylogeny, we followed Abrego et al. (2017) and used as a proxy for the phylogenetic correlation matrix **C** a taxonomical correlation matrix, constructed from the five levels of class, order, family, genus and species, and assumed equal branch length for each level. As a community-level random effect, implemented through a latent variable approach (Ovaskainen et al., 2017, 2016), we included the study site, with 12 levels.

We fitted the model to the data using the HMSC-R package (Tikhonov et al., 2019). We assumed the default prior distributions, and sampled the posterior distribution for 150*thinning iterations, out of which the first 50*thinning iterations were discarded as burn-in. We used thinning=100 and thus run the MCMC chain for a total of 15,000 iterations. We assessed the convergence of the MCMC chain visually, and examining the convergence of the results between thinning=1, thinning=10, and thinning=100.

To examine host-tree specialization at the levels of species and functional groups, we used the fitted model to predict species occurrences to new sampling units that were standardized to be of average size and decay stage and consisted of each of the four host-tree species. To examine host-tree specialization at the species level, we used these predictions to classify the host-tree use of each fungal species to one of the following seven classes: generalist, coniferous generalist, spruce specialist, pine specialist, broadleaved generalist, birch specialist, and aspen specialist. We first classified the species as generalists, broadleaved species or coniferous species by asking whether the predicted mean occurrence probability over broadleaved trees (birch and aspen) was smaller or greater than that for coniferous trees (pine and spruce) with at least 95% posterior probability. We further classified the broadleaved species as aspen specialists, birch specialists or broadleaved generalists by examining if the occurrence probability on aspen was smaller or greater than that for birch with at least 95% posterior probability. Similarly, we classified the coniferous species as spruce specialists, pine specialists and coniferous generalists.

To examine host-use specialization at the functional group level, we counted for each seven host-tree use classes the numbers of species belonging to each of the seven fruitbody types. We then asked if a particular fruitbody type was over- or underrepresented in a given host-tree type by conducting a randomization test, in which we randomly permuted the fruitbody types among the species, and examined if the observed value was greater or smaller than the 95% quantile in 1000 randomizations. To examine the association among host-tree use and spore-related traits (presence of ornamentation and the shape and size of spores), we computed the posterior distributions of community-weighted mean traits for species predicted to occur on each of the four tree species.

RESULTS

Morphological traits and species richness

In total, we recorded 657 species in total, which occurred 5714 times (Appendix 1). A large proportion of the species was resupinates (288 species, 44%), followed by discomycetes (148, 22.5%), agaricoids (73, 11%), pyrenomycetoids (71, 11%), pileates (49, 7%), stromatoids (18, 3%), and ramarioids (10, 1.5%).

Aspen dead wood had the highest fungal species richness (239 spp.), followed by birch (221), spruce (209) and pine (186). All tree species shared 68 species, on top of which the two broadleaved species shared 107 species, the two conifers shared 70, whereas all other combinations of coniferous and broadleaved tree species shared less than 20 fungal species. Discomycetoids, pyrenomycetoids, ramarioids and stromatoids had significantly higher species richness on broadleaved host trees than on conifers (Supplementary Material 3).

Spore size (volume) and shape (length/width) showed a weak but statistically significant negative association (in linear regression, p=0.02, R^2=0.008). While pyrenomycetoids had the largest and most elongated spores, agaricoids had large and spherical spores, whereas pileates and resupinates had the smallest spores (Fig. 1).

Effects of environmental variables on community composition

The fitted joint species distribution model explained 6% of the variation in the fungal community composition, as measured by the average Tjur (2009) R^2 value over the species. Of the variables included in the model, host-tree species was by far the most important one, as 71% of the explained variation in species occurrence was attributed to it. The percentages of explained variation attributed to other variables were 15% for log-characteristics (size and decay class), 5% for forest naturalness, and 9% for the random effect of the site. Considering only associations that had at least 95% posterior support, the occurrence probability of 86 species increased and of 0 species decreased with the size of the log, 16 species preferred decay class 3 and 11 species decay class 2, and the occurrence probability of 10 species increased and of 1 species decreased with the increasing value of the naturalness index.

Among the 293 species that occurred at least four times in the data, 66 were generalists, 95 broadleaved generalists, 30 birch specialists, 14 aspen specialists, 41 coniferous specialists, 27 spruce specialists and 20 pine specialists (Fig. 2).

Effects of morphological traits on the responses to the environment

The traits explained 7% of the variation in the species responses to the environmental variables. The posterior mean of the phylogenetic signal parameter ρ was 0.20 and its 95% credibility interval was [0.11, 0.35]. As the prior for ρ has probability mass of 0.5 at $\rho = 0$ (no phylogenetic signal) and the remaining probability is distributed evenly in [0, 1], the model revealed a moderate but statistically well supported phylogenetic signal in species responses to environmental covariates. In other words, phylogenetically (taxonomically) related species showed more similar responses to the environmental covariates than could be predicted solely based on their traits. We recorded a large number of non-random associations between host-tree use and fruitbody type (Fig. 3). In particular, species with resupinate fruitbodies were typically conifer generalists, while species with pileate fruitbodies were often specialized to spruce. Species with discomycetoid fruitbody were typically broadleaved generalists, whereas species with pyrenomycetoid fruitbodies were often birch specialists.

The fungal species occurring on broadleaved dead wood had on the average larger spores than those occurring on coniferous dead wood (Fig. 4A). The fungal species occurring on aspen had the most elongated spores, whereas those occurring on spruce had the most spherical spores (Fig. 4B). The proportion of species with ornamented spores varied between 12% and 16% on all host trees, with birch having the largest and spruce the smallest proportion of species with ornamented spores (Fig. 4C). Larger logs had larger and more spherical spores, whereas smaller logs had smaller and more elongated spores (Fig. 4D-E). Spore ornamentation did not vary with log size (Fig. 4F).

DISCUSSION

Our study shows that the occurrence of fungal species in dead wood of different characteristics relates to the morphological traits of the fungal fruitbodies and sexual spores. While it is well known that many wood-inhabiting fungal species are specialized to certain host-tree species (Berglund et al., 2011; Küffer et al., 2008; Stokland et al., 2004; Stokland, 2012a), to our knowledge, this is the first time that the importance of the fruitbody and spore morphology in determining host-tree specialization is revealed. We next discuss in turn, how and why fruitbody and spore morphology are linked to host-tree identity.

Specialization to host-tree species was related to fruitbody morphology. In line with our hypothesis that species developing small-sized fruitbodies from the Ascomycota lineages are more prevalent on broadleaved wood, we found discomycetes to be specialized to broadleaved trees in general, and pyrenomycetes to birch in particular. This association may relate to the fact that broadleaved dead wood generally holds higher proportions of bark, which is possible to decompose only through the so called soft-rot carried out by some Ascomycota species (Stokland, 2012b). While we expected species with pileate and resupinate fruitbodies to be equally prevalent in broadleaved and coniferous wood, we found resupinate species to be specialized to conifer tree species in general and pileates to spruce in particular. Because of the small-scale of our study (forests from central Finland), it remains to be tested by larger scale studies whether this is a general pattern in wood-inhabiting fungal communities.

Our results also revealed an association between host tree species and spore size. Fungal species on broadleaved trees had on average larger spores than those inhabiting conifers. This result is in line with Kauserud et al. (2008) who found that polypore species inhabiting broadleaved dead wood had significantly larger spores than species inhabiting coniferous dead wood. They speculated that because coniferous trees are evolutionary older, their wood is easier to penetrate and thus colonizing spores do not need as much energy and inoculum potential as spores colonizing broadleaved trees. Our results show that this may also relate to the relationship between fruitbody morphology and spore size, as pyrenomycetoids had on average the largest and most elongated spores, and they were also as a group specialized on broadleaved trees (birch in particular).

We expected aspen dead trees to hold species with smaller spores, because these trees show clustered and isolated distributional patterns in the boreal forest landscape, and smaller spores are able to disperse larger distances (Norros et al., 2014). Yet, our results showed the contrary, the fungal species occurring on broadleaved dead wood having on average larger, and more specifically more elongated, spores. Some studies have suggested that spore elongation increases attachment to substrate (Calhim et al., 2018; Ingold, 1965). It remains to be tested what is the primary reason pushing larger spore size on species inhabiting broadleaved trees.

Considering the relationship between log characteristics and spore morphology, previous studies have reported weak and/or contrasting results (e. g. Nordén et al. 2013; Abrego et al. 2017). Interestingly, we found a clear relationship between spore size and shape and the log size. Species with spherical and large spores preferred large logs, whereas species with elongated and small spores preferred smaller logs. Bässler et al. (2014) hypothesized that wood-inhabiting fungal species with smaller and more elongated spores, follow the *r* reproductive strategy (sensu Grime 1988), and thus cope better in managed environments where dead wood items are typically smaller. We cannot conclude how spore morphology relates to the *K*/*r* reproductive strategy since we did not collect data about spore production. Yet, our results are in line with Bässler et al.'s (2014) hypothesis that species with smaller and more elongated spores occur more often in smaller dead trees; thus, their proportion can be expected to be higher in forests where most dead wood is small due to management actions (Abrego and Salcedo, 2013; Eräjää et al., 2010).

Spore ornamentation is not likely to influence airborne dispersal substantially (Hussein et al., 2013) but may be important for attaching to animal vectors for dispersal. Especially mycorrhizal species are characterized by ornamented spore walls (Halbwachs et al., 2015), which are suggested to aid in transportation to deeper soil layers via arthropod vectors (Calhim et al., 2018). As mycorrhizal species only utilize decaying logs for attaching their fruitbodies, it is logical that we did not find clear differences in spore ornamentation frequency between different tree species. However, the role of mycorrhizal fungi might be minor in the present study. The rationale is that the occurrence of mycorrhizal wood-inhabiting fungal species increases in the last decay stages (Mäkipää et al., 2017; Rajala et al., 2015), and our study included only intermediate decay stages. Moreover, the proportion of species with ornamented spores was equal in totally saprotrophic groups (ramarioids and stromatoids) and a group encompassing many mycorrhizal fungi (resupinates) (Kotiranta et al., 2009). However, we treated ornamentation as a bipartite yes/no variable although we acknowledge that there is a lot of variation within the different types of ornamentation and the role of different ornamentation types deserves more research attention.

We note that the vast majority of the variation in species occurrences at the level of logs was not explained by the fitted model. This result is in accordance with previous studies from temperate Europe (Abrego et al., 2017, 2014; Bässler et al., 2012), which concluded that random processes dominate in shaping wood-inhabiting fungal communities at small spatial scales. Most fungal species were rare (55% occurring three or fewer times), which is a common feature of ecological communities in which random processes are dominating (Vellend, 2016; White et al., 2006). However, there might be many other variables we did not include, but which could have improved the models predictive power, such as microclimatic factors or direct measurements on wood composition such as C/N ratio. This result was also partially influenced by the fact that we conducted only two surveys, one in each of the peak fruiting season in boreal forests (Abrego et al., 2016; Halme and Kotiaho, 2012; Purhonen et al., 2017). Since many wood-inhabiting fungi have ephemeral fruitbodies, repeating surveys over several years in the peak fruiting seasons would have decreased the proportion of rare species and thus increased the predictive power of our model. Also molecular surveys of mycelia would have possibly decreased the proportion of rare species and increased predictability of their occurrence (e.g. Kubartová *et al.* 2012; Mäkipää *et al.* 2017). However, in comparison to molecular surveys, fruitbody based surveys provide direct information about the "breeding" populations of fungi. As a large portion of the species groups in the present study is taxonomically poorly known, some of the results should be considered with caution. For example *Mollisia* sp., which were found to share several host-tree species, might indeed be specialized in different host trees (see also Runnel *et al.* 2014).

We found that broadleaved dead trees hold higher species richness than coniferous dead trees. In particular, aspen hosted the highest and pine the lowest species richness. Higher species richness in broadleaved trees may result from the lack of defensive chemicals that conifer tree species have, making them easier to colonize and decay (Hoppe et al., 2016; Stokland, 2012a). However, fungal fruiting patterns may differ between tree species, and thus to observe the true differences in species richness between tree species, fruitbody surveys should be accompanied with molecular data of mycelia within wood. Furthermore, different tree species have different residence times, and thus the total species richness may be higher for tree species with longer life-span as a log.

Conclusions

Our study showed that the occurrence of fungal species in dead wood of different characteristics is related to the morphological traits of fungi. Our results also revealed that specialization to host-tree species occurs at the level of fruitbody morphological groups, and that the size and shape of the fungal spores relate to the preference for logs of different sizes.

Acknowledgements

We are grateful to Katja Juutilainen for contributing to the fungal surveys, Titta Kauppinen for help with dead wood and trait data collection and Leena Nikolajev-Wikström for trait data collection. Anni Rintoo, Jorma Pennanen, Matti Kulju, Unto Söderholm, Timo Kosonen and Tea von Bonsdorff helped with identification of difficult fungal specimens. We want to thank also Panu Kuokkanen from Metsähallitus for providing the forest age information of the study sites. We also thank the two anonymous reviewers for their constructive comments on an earlier version of the manuscript. This study was funded by the Ministry of the Environment (PUTTE grant to Halme), the Finnish Foundation of Nature Conversation and the Finnish Cultural Foundation (grants to Purhonen), Academy of Finland (grants 309581 and 284601 to Ovaskainen and grant 308651 to Nerea Abrego), Jane and Aatos Erkko Foundation (grant to Ovaskainen), and Research Council of Norway through its Centres of Excellence Funding Scheme (223257) to Ovaskainen via Centre for Biodiversity Dynamics.

Figure captions:

Fig. 1 Relationship between spore morphological traits and fruitbody types. The relationship between (A) the fruitbody type and spore volume, (B) spore shape, (C) and spore ornamentation.

Fig. 2 Numbers of host-tree generalist and specialist fungal species. The bars show the numbers of fungal species classified to the seven host-tree specialization classes, with colours representing different fruitbody types. Note that the figure includes only those species that occur at least four times in the data, as reliable classification for host-tree specialization is not possible for rare species.

Fig. 3 Host-tree specialization-level of fungi with different fruitbody types. Green colours (respectively, red colours) indicate that the fungal species groups have a given host-tree classification more often (respectively, less often) than expected by random, the asterisks indicating those results that are supported by at least 95% posterior probability. Note that this analysis is restricted to those species that occur at least 4 times in the data.

Fig. 4 Community-weighted mean spore trait values for different host-tree species (panels A-C) and for logs of different sizes (panels D-F). The first column shows the mean spore volume, the second column shows the mean spore shape, and the third column shows the mean proportions of species with ornamented spores. The error bars (panels A-C) and shaded areas (panels D-F) show the 95% credibility interval.

Supplementary Material 1

Detailed description of the forest naturalness index

The study site naturalness was calculated based on the average age of the dominating forest cover (data received from the State Forest Enterprise of Finland), the average amount of dead wood per hectare, and the average number of stumps per hectare. The dead wood and stump data were collected from four to eight, 50 meter in length and 10 meter wide, randomly placed transects. The transects were situated in the same forest stands in which the logs were surveyed for fungi. The number of transects varied depending on the characteristics of the study site. If there was clear within-site variation in the forest types surrounding the study logs, we established 2-4 additional transects. The transects were inspected for all dead wood units larger than 15 cm at the base. We measured the length, base diameter and top diameter (this information was later used for calculating the volume of the dead wood with the formula of a truncated cone) for standing and grounded dead wood. We also recorded the number of stumps. Transect data was then used to count average values for each of the variables at the transect level. We divided these values by 0.05 for estimating the average values per hectare. The sites were then sorted according to each of the above variable separately and a score from 1 to 12 was given depending on the site position. Sites with higher average age, more dead wood and fewer stumps were given more points and considered being more natural. The points of each forest were summed up to form the “forest naturalness index” (Table 1).

Table 1 The age of dominating forest cover in years and amount of deadwood (m^3/ha) and number of stumps per hectare for each study site. Corresponding naturalness index-value for each site is the sum of the points. The sites are sorted according to their Index-values from most natural to least.

Site	Age / Deadwood / Stumps	Points	Index
Latokuusikko	173 / 334 / 0	11 / 12 / 12	35
Pyhä-Häkki	272 / 98 / 39	12 / 9 / 11	32

Supplementary material 2

TABLE 1 List of detected species or taxonomic groups in alphabetical order. The trait data are shown for fruitbody type (7 categories, see Methods), spore volume (µm^3, calculated with the formula of using species-specific mean spore length and width), shape (species-specific mean length of the spore divided by its width) and ornamentation (Yes, No). The information was extracted from literature (below) or by measuring/ observing by the authors.

Species or taxa name	Fruit body type	Volume	Shape	Orn	Birch	Spruce	Pine	Aspen	Total
Acanthostigma sp1.	Pyrenomycetoid	96.40	2.24	No	-	1	-	1	2
